ABSTRACT: The measurements of the properties of the Higgs boson still leave room for a non minimal scalar sector. Extensions of the Standard Model typically involve multiple neutral Higgs fields which can interfere among themselves. We show that these interference effects can be substantial taking as example the one Higgs Singlet Model, the simplest renormalizable addition to the SM.

1 Introduction

All measurements performed in LHC Run I relative to the resonance discovered at about 125 GeV [1, 2] are consistent with the hypothesis that the new particle is indeed the Standard Model Higgs boson. While the mass is already known to an astonishing three per mill from the latest published CMS measurement [3], the signal strengths $\mu^i = \sigma^i/\sigma_{SM}^i$, where i runs over the decay channels, are known to about 10 to 20% [3–5]. This leaves room for modifications of the SM with a more complicated Higgs sector provided they are consistent within experimental errors with the data. A larger Higgs sector implies that additional scalar states are present in the spectrum. Direct searches have provided limits on the existence of new spin zero particles and on the strengths of their couplings [6]. The larger luminosity and energy in Run II will allow more precise measurements of the already discovered Higgs properties and extend the mass range in which other scalars can be searched for.

The simplest renormalizable extension of the SM is the one Higgs Singlet Model (1HSM). It introduces one additional real scalar field which is a singlet under all SM gauge groups. The 1HSM has been extensively investigated in the literature [7–28], however, to our knowledge, no public MC implementation of the model is available. In this note we present such an implementation using FeynRules for the derivation of the vertices and Madgraph 5 for the generation of the amplitudes. We then discuss the simple case of Higgs production via gluon fusion at the LHC.

2 The Singlet Extension of the Standard Model

The singlet extension of the SM is defined by adding to the standard Lagrangian the following gauge invariant, renormalizable term:

$$\mathcal{L}_s = \partial^\mu S \partial_\mu S - \mu_1^2 \Phi^\dagger \Phi - \mu_2^2 S^2 + \lambda_1 (\Phi^\dagger \Phi)^2 + \lambda_2 S^4 + \lambda_3 \Phi^\dagger \Phi S^2. \quad (2.1)$$

where S is a real $SU(2)_L \otimes U(1)_Y$ singlet and Φ , is the SM Higgs weak isospin doublet. Here and in the following we adopt the notation of ref. [23]. A \mathcal{Z}_2 symmetry which forbids additional terms in the potential is assumed. A detailed discussion of the 1HSM without \mathcal{Z}_2 symmetry can be found in ref. [26].

The neutral components of these fields can be expanded around their respective Vacuum Expectation Values (VEVs) as follows:

$$\Phi = \begin{pmatrix} G^\pm \\ \frac{v_d + l^0 + iG^0}{\sqrt{2}} \end{pmatrix} \quad S = \frac{v_s + s^0}{\sqrt{2}}. \quad (2.2)$$

The minimum of the potential is achieved for

$$\mu_1^2 = \lambda_1 v_d^2 + \frac{\lambda_3 v_s^2}{2}; \quad \mu_2^2 = \lambda_2 v_s^2 + \frac{\lambda_3 v_d^2}{2}, \quad (2.3)$$

provided

$$\lambda_1, \lambda_2 > 0; \quad 4\lambda_1\lambda_2 - \lambda_3^2 > 0. \quad (2.4)$$

The mass matrix in the gauge basis can be diagonalized into the (tree-level) mass basis introducing new fields:

$$h = l^0 \cos \alpha - s^0 \sin \alpha \quad \text{and} \quad H = l^0 \sin \alpha + s^0 \cos \alpha \quad (2.5)$$

with $-\frac{\pi}{2} < \alpha < \frac{\pi}{2}$.

The masses are

$$m_{h,H}^2 = \lambda_1 v_d^2 + \lambda_2 v_s^2 \mp |\lambda_1 v_d^2 - \lambda_2 v_s^2| \sqrt{1 + \tan^2(2\alpha)}, \quad \tan(2\alpha) = \frac{\lambda_3 v_d v_s}{\lambda_1 v_d^2 - \lambda_2 v_s^2}, \quad (2.6)$$

with the convention $m_H^2 > m_h^2$. They correspond to a light $[h]$ and a heavy $[H]$ \mathcal{CP} -even mass-eigenstate.

The Higgs sector in this model is determined by five independent parameters, which can be chosen as

$$m_h, m_H, \sin \alpha, v_d, \tan \beta \equiv v_d/v_s, \quad (2.7)$$

where the doublet VEV is fixed in terms of the Fermi constant through $v_d^2 = G_F^{-1}/\sqrt{2}$. Furthermore one of the Higgs masses is determined by the LHC measurement of 125.02 GeV. Therefore, three parameters of the model are presently free.

As only the doublet component, before mixing, can couple to the fermions (via ordinary Yukawa interactions) and the gauge bosons (via the gauge covariant derivative), all of the corresponding Higgs couplings are rescaled universally, yielding

$$g_{xsh} = g_{xsh}^{\text{SM}}(1 + \Delta_{xs}) \quad \text{with} \quad 1 + \Delta_{xs} = \begin{cases} \cos \alpha & s = h \\ \sin \alpha & s = H \end{cases}. \quad (2.8)$$

Figure 1. On the left: the partial width for the $H \rightarrow hh$ process for $s_\alpha = 0.3, 0.2, 0.1$ and $\tan \beta = 1.0$. On the right: the corresponding branching ratios.

$$g_{xxs_1s_2} = g_{xxhh}^{\text{SM}}(1 + \Delta_{xs_1})(1 + \Delta_{xs_2}). \quad (2.9)$$

where xx represents a pair of SM fermions or vectors.

The couplings in the scalar sector involve $\tan \beta$ and are slightly more complicated. As an example we reproduce the triple scalar vertices in terms of the independent parameters mentioned above ($s_\alpha = \sin \alpha$, $c_\alpha = \cos \alpha$):

$$V_{hhh} = -\frac{3ieM_h^2}{2M_W s_W} \{c_\alpha^3 - s_\alpha^3 \tan \beta\} \quad (2.10)$$

$$V_{hHH} = -\frac{ies_\alpha c_\alpha}{2M_W s_W} \{s_\alpha - c_\alpha \tan \beta\} \{M_h^2 + 2M_H^2\} \quad (2.11)$$

$$V_{Hhh} = -\frac{ies_\alpha c_\alpha}{2M_W s_W} \{c_\alpha + s_\alpha \tan \beta\} \{2M_h^2 + M_H^2\} \quad (2.12)$$

$$V_{HHH} = -\frac{3ieM_H^2}{2M_W s_W} \{s_\alpha^3 + c_\alpha^3 \tan \beta\} \quad (2.13)$$

The tree level partial width for the decay of the heavy scalar into two light ones reads:

$$\Gamma(H \rightarrow hh) = \frac{e^2 M_H^3}{128\pi M_W^2 s_W^2} \left(1 - \frac{4M_h^2}{M_H^2}\right)^{\frac{1}{2}} \left(1 + \frac{2M_h^2}{M_H^2}\right)^2 s_\alpha^2 c_\alpha^2 (c_\alpha + s_\alpha \tan \beta)^2 \quad (2.14)$$

In fig. 1 we show the partial width and the corresponding branching ratios as a function of the heavy Higgs mass for $s_\alpha = 0.3, 0.2, 0.1$ and $\tan \beta = 1.0$. The BR is computed as the ratio of the lowest order width in eq.(2.14) to the total width given in ref. [29] multiplied by s_α^2 . The BR rises sharply above the kinematical threshold and, for the parameter range we have considered, remains larger than 25% up to $M_H = 1$ TeV. This raises the tantalizing prospect of a relatively abundant production of heavy Higgses followed by their decay into two light ones if $M_H > 2M_h$. See ref. [26] for a detailed discussion in the framework of the 1SHM.

3 Limits on the parameters

The strongest limits on the parameters of the 1HSM come from measurements of the coupling strengths of the light Higgs [3–6], which dominate for small masses of the heavy Higgs, and from the contribution of higher order corrections to precision measurements, in particular to the mass of the W boson [24], which provides the tightest constraint for large M_H . The most precise result for the overall coupling strength of the Higgs boson from CMS [3] reads

$$\hat{\mu} = \hat{\sigma}/\sigma_{SM} = 1.00 \pm 0.13. \quad (3.1)$$

Therefore the absolute value of $\sin \alpha$ cannot be larger than about 0.4. This is in agreement with the limits obtained in ref. [24, 27] which conclude that the largest possible value for the absolute value of $\sin \alpha$ is 0.46 for M_H between 160 and 180 GeV. This limit becomes slowly more stringent for increasing heavy Higgs masses reaching about 0.2 at $M_H = 700$ GeV.

4 Interference effect and simulation tools

The focal point of this note is the interference between the two Higgs fields. In general, any amplitude involving a single Higgs exchange can be written as

$$A = A' \left(\frac{c_\alpha^2}{q^2 - M_h^2 + i\Gamma_h M_h} + \frac{s_\alpha^2}{q^2 - M_H^2 + i\Gamma_H M_H} \right) + A_0 = A_1 + A_0 \quad (4.1)$$

where A_0 does not involve the scalar fields. The real parts of the two propagators interfere destructively for $M_h^2 < q^2 < M_H^2$ and constructively for $q^2 < M_h^2$ and $M_H^2 < q^2$. This phenomenon has already been noticed in ref. [25] where however it was dismissed as numerically irrelevant.

As will be argued in sect. 5, the interference effects can be substantial, their relevance increasing with M_H . The shape of the heavier Higgs peak is also strongly affected and

this will need to be taken into account in any search for additional scalars and eventually in the measurement of their properties.

These features are neglected by any prediction based on the narrow width approximation, or equivalently on a production times decay approach.

The relevance of the interference term does depend on the relative size of A_0 and A_1 in eq.(4.1) and is expected to be significant for processes in which the resonant part of the amplitude is large as in gluon fusion for large values of the heavy Higgs mass.

Clearly, this interference between different Higgs fields is not a peculiarity of the Singlet Model. It will indeed occur in any theory with multiple scalars which couple to the same set of elementary particles, albeit possibly with different strengths.

In order to allow for the Monte Carlo simulation of the 1HSM we have used FeynRules [30, 31] to prepare a UFO file [32] for the model, which can be imported, as we did, in MadGraph 5 [33] and many other general purpose MC tools. It enables the simulation at tree level of any process in the 1HSM. The UFO file can be downloaded from <http://personalpages.to.infn.it/~maina/Singlet>.

The gluon fusion channel in MadGraph requires particular care. MadGraph treats the gluon-Higgs effective vertex in the narrow width approximation, through an expansion of the top loop amplitude in powers of M_h^2/M_{top}^2 , which is unsuitable in the present context and which fails for Higgs masses above the t-tbar threshold. The appropriate effective vertex V_{ggh} must be introduced by hand in the matrix element:

$$V_{ggh} = -i \frac{2\alpha_s(\sqrt{2}G_F)^{\frac{1}{2}}M_{top}^2}{\pi\hat{s}} \left(1 - \frac{1}{2}(1-\tau)C(\tau)\right), \quad (4.2)$$

with

$$C(\tau) = \begin{cases} -2 \arcsin(1/\sqrt{\tau})^2 & \tau > 1 \\ \frac{1}{2} \left(\log\left(\frac{1+\beta}{1-\beta}\right) - i\pi \right)^2 & \tau < 1 \end{cases} \quad (4.3)$$

where $\tau = 4M_{top}^2/\hat{s}$, $\beta = \sqrt{1-\tau}$ and \hat{s} is the square of the sum of the momenta carried by the gluons which in general is not equal to the Higgs mass squared.

The tensor structure of the vertex is already taken care of by MadGraph.

5 Results

As an example we have studied Higgs production through gluon fusion in the four electron channel, $gg \rightarrow h, H \rightarrow ZZ \rightarrow 4e$, at the LHC with a center of mass energy of 13 TeV.

We neglect the non resonant contribution given by $q\bar{q} \rightarrow ZZ$ and by $gg \rightarrow ZZ$ through a quark box amplitude. This continuum is known to be large and in particular there is a non negligible interference between the box contribution and Higgs production through the heavy quark three point loop. These terms are well known [34–47] and are essential for accurate phenomenological predictions. The region of large invariant masses of the four final state leptons in $gg \rightarrow ZZ, WW \rightarrow 4l$ has been studied in detail in ref. [47] in the SM with a Higgs of 125 GeV. Above the light Higgs peak, the differential cross

section is dominated by the continuum for $M_{4l} < 2M_{top}$. The box contribution however drops more rapidly with increasing M_{4l} than the Higgs mediated one. Unitarity requires the interference between these two components to be negative and while it is essentially negligible below the top threshold it becomes more relevant for larger masses and exceeds 50% of the incoherent sum of the two contributions in the one TeV range.

Figure 2. $gg \rightarrow h, H \rightarrow ZZ \rightarrow 4e$ at the LHC with a center of mass energy of 13 TeV. Upper part: four lepton invariant mass distribution for $M_h = 125$ GeV, $M_H = 400$ GeV and $s_\alpha = 0.2$. The red line is the full result (σ). The violet histograms (σ_h) shows the SM prediction with Higgs couplings scaled by $\cos \alpha$. The blue line (σ_H) gives the result when the light Higgs diagrams are neglected while the $H \rightarrow hh$ contribution to Γ_H is retained. The black histogram (σ_{NI}) refers to the sum of the violet and blue lines and corresponds to neglecting the interference effects. Lower part: the ratio $\frac{\sigma - \sigma_{NI}}{\sigma_{NI}}$.

Figure 3. Four lepton invariant mass distribution for $M_h = 125$ GeV, $M_H = 400$ GeV, $s_\alpha = 0.3$. The meaning of the various histograms is as in fig. 2.

Our main results are shown in figs. 2–5 and tab. 1. No cut has been applied to the final state. We have used CTEQ6L1 parton distribution functions [48]. The ratio of vacuum expectation values $\tan\beta$ has been taken equal to one.

The width of the light and heavy scalar are

$$\Gamma_h = \Gamma^{SM}(M_h)c_\alpha^2, \quad \Gamma_H = \Gamma^{SM}(M_H)s_\alpha^2 + \Gamma(H \rightarrow hh). \quad (5.1)$$

This corresponds, using eq.(2.14) for the $H \rightarrow hh$ width and ref. [29] for the SM Higgs width, to $\Gamma_H = 1.77(4.08)$ GeV for $M_H = 400$ GeV, $s_\alpha = 0.2(0.3)$; $\Gamma_H = 15.80$ GeV for $M_H = 600$ GeV and $s_\alpha = 0.3$; $\Gamma_H = 16.69$ GeV for $M_H = 800$ GeV and $s_\alpha = 0.2$. We have assumed $M_h = 125$ GeV which corresponds to $\Gamma^{SM}(125) = 4.03$ MeV.

Figure 4. Four lepton invariant mass distribution for $M_h = 125$ GeV, $M_H = 600$ GeV, $s_\alpha = 0.3$. The meaning of the various histograms is as in fig. 2.

	200 GeV < M_{4l} < 1 TeV			$M_H - 25$ GeV < M_{4l} < $M_H + 25$ GeV		
	σ	$\sigma_h + \sigma_H$	σ_H	σ	$\sigma_h + \sigma_H$	σ_H
$M_H = 400$ GeV, $s_\alpha = 0.2$	72.95	70.96	26.00	32.09	32.13	25.55
$M_H = 400$ GeV, $s_\alpha = 0.3$	101.48	96.51	55.99	60.36	59.70	53.74
$M_H = 600$ GeV, $s_\alpha = 0.3$	48.44	52.52	11.99	11.51	11.96	9.97
$M_H = 800$ GeV, $s_\alpha = 0.2$	43.96	45.96	1.00	1.57	1.46	0.65

Table 1. Cross sections in ab for $gg \rightarrow h, H \rightarrow ZZ \rightarrow 4e$ at the LHC with a center of mass energy of 13 TeV.

Figure 5. Four lepton invariant mass distribution for $M_h = 125$ GeV, $M_H = 800$ GeV, $s_\alpha = 0.2$. The meaning of the various histograms is as in fig. 2.

We show the region around the heavy Higgs peak where the interference affects are most prominent. The invariant mass distribution in the neighborhood of the light Higgs resonance is unaffected within the accuracy of the present simulation. In all figures the violet histogram is the result obtained including only the light Higgs with SM couplings scaled by c_α which we denote as σ_h . Since Γ_h is small $\sigma_h \approx \sigma_{SM}(M_h)c_\alpha^4$ for large M_{4l} . The blue line shows the cross section when only the heavy Higgs is present, which will be referred to as σ_H . The $H \rightarrow hh$ contribution to Γ_H is retained and therefore σ_H is not equal to $\sigma_{SM}(M_H)s_\alpha^4$. The full result, σ , is shown in red in fig. 2 for $s_\alpha = 0.2$, $M_H = 400$ GeV, in figs. 3, 4 for $s_\alpha = 0.3$ with $M_H = 400$ GeV and $M_H = 600$ GeV respectively and finally in fig. 5 for $s_\alpha = 0.2$, $M_H = 800$ GeV. The black histogram displays the sum of the blue and violet lines, $\sigma_{NI} = \sigma_h + \sigma_H$, and corresponds to neglecting the interference

between the two scalars. The fractional size of the correction to σ_{NI} is displayed in the bottom part of the figures where the ratio of the interference term and σ_{NI} , $\frac{\sigma - \sigma_{NI}}{\sigma_{NI}}$, is shown.

Contrary to naive expectations the light Higgs contribution is non negligible outside the peak region [47] and the interference effect is substantial. While the details depend obviously on the mass of the heavy Higgs and on the mixing angle, we find a decrease of 10 to 20% of the differential cross section at invariant masses of the four leptons of 300 GeV for $M_H = 400$ and of about 20% for $M_{4l} = 350$, $M_H = 600$ and for $M_{4l} = 500$, $M_H = 800$. This depletion becomes more pronounced as M_{4l} increases and reaches a dip which is almost two orders of magnitude smaller than the predictions which neglect the interplay of the two Higgs fields. The interference stays negative for four lepton masses below the heavy Higgs mass and then turns positive. It attains a maximum in which the true value is about a factor of two larger than σ_{NI} and then slowly decreases. The position of the peak is shifted to slightly larger masses. At four lepton masses about 200 GeV larger than M_H the interference still amounts to about 20 to 40% of σ_{NI} . Because of unitarity, for very large M_{4l} the full cross section σ must approach the SM result σ_{SM} . In this region, where the width of the two Higgses can be neglected, $\sigma_{SM} = \sigma_h/c_\alpha^4 = \sigma_H/s_\alpha^4$.

tab. 1 shows the cross section in ab for two mass intervals: $200 \text{ GeV} < M_{4l} < 1 \text{ TeV}$, which roughly coincides with the range employed so far by the experimental collaborations to set limits on the presence and couplings of additional scalars, and $M_H - 25 \text{ GeV} < M_{4l} < M_H + 25 \text{ GeV}$, as an indication of the possible effects on an analysis in smaller mass bins which requires high luminosity. In the first case, the contribution of the heavy Higgs is a relatively small fraction of the Higgs production cross section in gluon fusion. Furthermore, the interference effects in the $200 \text{ GeV} < M_{4l} < 1 \text{ TeV}$ depend crucially on the heavy Higgs mass. For $M_H = 400$ the exact result is larger than the incoherent sum $\sigma_h + \sigma_H$. The long tail for $M_{4l} > M_H$ gives a larger contribution than the intermediate region $200 \text{ GeV} < M_{4l} < M_H$. On the contrary, for larger heavy Higgs masses we have $\sigma < \sigma_h + \sigma_H$. The negative interference in the intermediate region outweighs the positive contribution at larger masses. In the smaller range, $M_H - 25 \text{ GeV} < M_{4l} < M_H + 25 \text{ GeV}$, the positive and negative contributions are very close for $M_H = 400 \text{ GeV}$ and the full result is in rough agreement with $\sigma_h + \sigma_H$. For this value of M_H and mass interval, the heavy Higgs contribution is significantly larger than the light Higgs one. For $s_\alpha = 0.3$, $M_H = 600 \text{ GeV}$ the exact cross section is about 4% smaller than the incoherent sum while for $s_\alpha = 0.2$, $M_H = 800 \text{ GeV}$ it is approximately 8% larger. We see that for large values of the heavy Higgs mass the interference effects are non negligible even on a restricted mass range.

Our results have no pretense to be a complete prediction. They need to be validated with the inclusion of the continuum contribution and of higher order corrections. It should be noticed that, for Higgs decay to color neutral final states, all relevant amplitudes in QCD will have the structure of eq.(4.1) and therefore interference effects between the scalar fields will not be spoiled by QCD corrections.

The interference with the quark box amplitude deserves more care. The gluon-gluon continuum term does not involve scalar exchanges and therefore it cannot be cast in the form of eq.(4.1) and could in principle dilute the effect. However, the interference between

the box diagrams and the light Higgs mediated ones is always negative, while the amplitude with a heavy Higgs exchange changes sign at the resonance. As a consequence the continuum and the heavy Higgs term are expected to be in phase for $M_h < M_{A\ell} < M_H$ and out of phase for $M_{A\ell} > M_H$. A detailed study of this topic is in preparation.

6 Conclusions

In any theory with multiple neutral Higgs which couple to the same set of elementary particles the scalars are expected to interfere. We have shown in the case of Higgs production through gluon fusion in the 1SHM that the interference effects can be significant and cannot be neglected when aiming for high accuracy predictions.
